Abstract

An atmospheric attenuation model for the ultraviolet, visible, and infrared was developed in 1964, based on scattering (molecules and aerosols) and ozone absorption. Since then more measurements have been made and our knowledge of aerosol attenuation has widened. These circumstances result in attenuation model changes which are relatively unimportant for most exploratory calculations. They can be significant, however, for long slant-path high-altitude applications entailing large zenith angles, factors which characterize, for example, the measurement geometries of rockets and satellites. Accordingly, a revision of the 1964 Attenuation Model is warranted.

In this paper the optical parameters are computed spectrally and with altitude as follows: (1) pure air attenuation parameters are determined by utilizing Rayleigh scattering cross sections with molecular number densities from the standard atmosphere; (2) ozone absorption parameters are derived based on Vigroux's coefficients applied to a representative atmospheric ozone distribution; (3) seven sets of aerosol measurements are compared and a profile of aerosol attenuation coefficients vs altitude is developed. Attenuation coefficients and optical thickness due to molecular, aerosol, and ozone attenuation are computed and tabulated individually so that the influence of each can be compared. The newly derived tabulations permit various exploratory calculations, including horizontal, vertical, and slant-path transmission at kilometer intervals to an altitude of 50 km, individually for each attenuating component or for overall atmospheric extinction (molecular + ozone + aerosol).

UV, Visible, and IR Attenuation for Altitudes to 50 km, 1968

1. INTRODUCTION

In 1964, an atmospheric attenuation model was published (Elterman, 1964) which has been useful for a variety of exploratory calculations. Now a revision is warranted for reasons given in the abstract and Section 4 of this report. In this revision most of the earlier material is presented in summary form. The section on attenuation by Rayleigh scattering, however, is retained because the content leading to the derivation of the Rayleigh parameters is useful. In one instance, due to existing interest, the material is expanded, i.e., the tabulations which comprise the attenuation model now include aerosol and ozone optical thickness so that a comparison can be made of the relative importance of each attenuating component for vertical and slant paths.

The shortest wavelength considered is 0.27 microns. The use of shorter wavelengths would require a treatment of O_2 absorption. Also, attenuation is sufficiently severe so that interest in the shorter wavelength region for purposes of ultraviolet transmission below 50 km probably is limited. The longest wavelength used is 4.0 microns. Calculations for longer wavelengths are complicated by the presence of absorption bands of H_2O , CO_2 , and their wings. In between, a total of 22 wavelengths is chosen (Table 1) within the atmospheric windows and for the ultraviolet region where ozone absorption is important.

(Received for publication 25 March 1968)

Conceptually, the attenuation model starts with molecular densities from the latest published U.S. Standard Atmosphere (1962) followed by the addition of ozone and aerosol components. The meteorological range (M.R.) at sea level corresponds to about 25 km at 0.55μ wavelength. This choice serves a useful function because it permits including some important measurements conducted at $\lambda = 0.55\mu$. In addition, this wavelength customarily represents the phototopic region.

λ - Wavelength

m_s - Index of refraction (1013 mb, 15°C)

σ_r - Rayleigh scattering cross section

A_v - Absorption coefficient after Vigroux for pure O₃, smoothed values (1013 mb, 18°C)

2. RAYLEIGH PARAMETERS

A fundamental requirement for generating an accurate series of Rayleigh parameters is an exact determination of the index of refraction for the wavelengths of interest. With this known, the Rayleigh cross sections can be computed. This in turn permits computation of the Rayleigh attenuation coefficient and its variation with altitude as well as corresponding optical thickness values.

The index of refraction for a standard atmosphere (1013 mb, 15°C) specifically for the desired wavelengths used is determined by Edlen's (1953) expression

$$(m_s - 1)10^{-8} = 6432.8 + \frac{2949810}{146 - (\lambda^{-2})} + \frac{25540}{41 - (\lambda^{-2})} \quad (1)$$

where m_s = refractive index ,
 λ = wavelength (microns) .

Penndorf's (1957) computations using Eq. (1) demonstrate that the effect of water vapor can be neglected and the derived m_s values have negligible error for the spectral range from 0.2 to 20.0 microns.

The Rayleigh cross section is expressed by

$$\sigma_r(\lambda) = \frac{8\pi^3(m_s^2 - 1)^2}{3\lambda^4 N_s^2} \cdot \frac{6 + 3\delta}{6 - 7\delta} \quad (2)$$

where

σ_r = the Rayleigh scattering cross section (cm^2),
 λ = the wavelength (cm),
 m_s = the index of refraction of air at 15°C and 1013 mb pressure,
 N_s = the molecular number density at sea level for a standard atmosphere (cm^{-3}),
 δ = the depolarization factor.

The term $(6 + 3\delta)/(6 - 7\delta)$ accounts for the degree of depolarization attributable to the anisotropy of the atmospheric molecule. The depolarization factor has been determined by calculation and by laboratory measurement. The latest work of Gucker and Basu (1953) yields $\delta = 0.035$. The wavelengths of interest with the indices of refraction and Rayleigh cross sections [computed from Eqs. (1) and (2)] are listed in Table 1, and plotted in Figures 1 and 2.

Using the scattering cross sections, the Rayleigh coefficients are obtained with

Figure 1. Index of Refraction for 1013 mb and 15°C (Table 1),
 ○○○○ Represent Attenuation Model Wavelengths

Figure 2. Rayleigh Cross Section vs Wavelength (Table 1),
 ○○○○ Represent Attenuation Model Wavelengths

$$\beta_r(h, \lambda) = \sigma_r(\lambda) \cdot N_r(h) \cdot (10^5 \text{ cm/km}) \quad , \quad (3)$$

where

$$\begin{aligned} \beta_r &= \text{the Rayleigh attenuation coefficient (km}^{-1}\text{)} \quad , \\ \sigma_r &= \text{the Rayleigh scattering cross section (cm}^2\text{)}, \\ N_r &= \text{the molecular number density (cm}^{-3}\text{)} \quad . \end{aligned}$$

The values of $N_r(h)$ needed for Eq. (3) were obtained from the U.S. Standard Atmosphere and are listed in Table 2. This expression is used to compute an array of Rayleigh attenuation coefficients as a function of altitude for each wavelength.

With the Rayleigh attenuation coefficients determined, the optical thicknesses from sea level to some altitude h are computed by

$$\tau_r(h, \lambda) = \sum_0^h \bar{\beta}_r(h, \lambda) \Delta h \quad , \quad (4)$$

where

$$\begin{aligned} \tau_r &= \text{Rayleigh optical thickness (0 - h)} \quad , \\ \bar{\beta}_r &= \text{mean of the Rayleigh attenuation coefficients (km}^{-1}\text{)} \\ &\quad \text{for each altitude increment,} \\ \Delta h &= \text{altitude increment chosen as one km for these calculations.} \end{aligned}$$

The Rayleigh optical thickness for altitude h to space is obtained by the relationship

$$\tau_r'(h, \lambda) = \tau_r(\infty, \lambda) - \tau_r(h, \lambda) \quad , \quad (5)$$

where

$$\begin{aligned} \tau_r'(h) &= \text{Rayleigh optical thickness (h - } \infty \text{)} \quad , \\ \tau_r(\infty) &= \text{Rayleigh optical thickness (0 - } \infty \text{)} \quad . \end{aligned}$$

The term $\tau_r(\infty)$ was obtained by using Eq. (4) with the limits set between 0 and 80 km. Above 80 km, Stergis' (1966) calculations, based on N_2 , O_2 , and O as the principal atmospheric constituents, yield

$$\int_{80}^{\infty} \beta_r(h, \lambda) dh = \begin{cases} 3.6 \times 10^{-6} & , \lambda = 0.4 \mu \\ 6.7 \times 10^{-7} & , \lambda = 0.6 \mu \\ 2.1 \times 10^{-7} & , \lambda = 0.8 \mu \end{cases} .$$

These values approximate a constant 10^{-5} , that of the Rayleigh optical thickness for unity air mass. For our purposes then the integral can be neglected because the constant is small and applies to all wavelengths of interest.

h – Altitude; N_r – Molecular number density;
 D_3 – Ozone equivalent thickness

3. ABSORPTION PARAMETERS FOR ATMOSPHERIC OZONE

This section is a summary of the material used in the 1964 Attenuation Model.

The parameter for determining O_3 absorption as a function of altitude is the atmospheric ozone absorption coefficient expressed by:

$$\beta_3(h, \lambda) = A_v(\lambda) D_3(h) \quad , \quad (6)$$

β_3 = atmospheric ozone absorption coefficient (km^{-1}),

A_v = the pure ozone absorption coefficient (cm^{-1}) after Vigroux,

D_3 = the ozone equivalent thickness (cm/km).

Thus, the Vigroux coefficients (1953) listed in Table 1 in conjunction with the ozone concentrations, Table 2 and Figure 3, permit the computation of an array of atmospheric ozone absorption coefficients to 50 km for each of the desired wavelengths.

Figure 3. Representative Atmospheric Ozone Concentration Profile (Table 2). Values for: 0 to 30 km, based on Handbook of Geophysics and Space Environment (1965) 30 to 40 km, interpolated 40 to 50 km, based on London, Ooyama, and Prabhakara (1962)

The ozone optical thickness from sea level to altitude h , $\tau_3(h, \lambda)$, and the ozone optical thickness from some altitude h to space, $\tau'_3(h, \lambda)$, are included in the model tabulations. The expressions for deriving these parameters have the same form as Eqs. (4) and (5).

4. AEROSOL ATTENUATION

Of the various methods used to investigate aerosol attenuation, for the present we will consider optical techniques only because they are suited to this type of study. In this country, Newkirk and Eddy (1964) used solar aureole photometry; Penndorf (1954) analyzed solar radiation measurements from aircraft altitudes; Elterman's results (1966a,b), with searchlight probing, comprise a substantial number of profiles acquired in New Mexico for altitudes to about 34 km. In Australia, Crosby and Koerber (1962) used a balloon-borne integrating nephelometer. In the U.S.S.R., Kondratiev, et al. (1967), conducted balloon solar transmission measurements; Feoktistov (1965) analyzed photographs of the earth's horizon from the spacecraft Voschod; Rozenberg, et al. (1960) (1966), acquired their results with searchlight probing. The various results, as shown in Figure 4, were made comparable at $\lambda_1 = 0.55\mu$ by using the empirical relationship that the aerosol attenuation coefficient is inversely proportional to wavelength. For reasons of clarity, a substantial body of results was not included in Figure 4, as for example the twilight measurements by Rozenberg (1965), Volz and Goody (1962), the searchlight measurements by Spankuch (1967), analysis of twilight aureole photographs from the spacecraft Vostok-6 by Driving (1966), the aircraft measurements of sky brightness by Sandomirski, Al'tovskaia and Trifonova (1964), and aircraft nephelometry by Waldram (1945). Also, interesting results in the form of relative values have been obtained with optical techniques: the twilight measurements by Bigg (1964), the laser beam backscatter by Collis and Ligda (1966), by Clemeshaw, Kent, and Wright (1967), and by Grams and Fiocco (1967).

A consideration of all results shows, as does Figure 4, that the aerosol attenuation coefficient is a strongly fluctuating parameter and that average values based on an adequate number of measurements are necessary in order to establish a representative profile. The recent searchlight probing measurements (Elterman, 1966a and 1966b) appear representative based on several considerations. First, each profile was acquired by continuous measurement through both troposphere and stratosphere and with an altitude resolution approximating one km. In addition, a total of 119 profiles comprising absolute values of aerosol attenuation coefficients were determined for various times throughout the year. This represents a substantially larger sample than previously published. Further, such a quantity of

Figure 4. Aerosol Attenuation Coefficients vs Altitude at $\lambda_1 = 0.55\mu$.

Comparison of results:

- XXXX solar aureole, 2 balloon flights, Newkirk and Eddy (1964);
- ΔΔΔΔ solar radiation measured from aircraft, mean of 8 flights, Penndorf (1954);
- ++++ searchlight probing, mean of 105 profiles, Elterman (1966a) and (1966b);
- ⊙⊙⊙⊙ balloon integrating nephelometer, mean of 14 flights, Crosby and Koerber (1962);
- solar radiation measured from balloons, mean of 3 flights, Kondratiev et al. (1967);
- ▲▲▲▲ spacecraft horizon photography, analysis of 4 frames, Rozenberg (1966), Feoktistov (1965);
- ○ ○ ○ searchlight probing, mean for 5 nights, Rozenberg (1966)

results readily permits statistical treatment. Finally, we note that the mean of the 119 profiles falls reasonably well within the values determined by other researchers, a circumstance which tends to provide a measure of comfort.

In considering the suitability of the 119 profiles, extensive averaging is required and this tends to wash out features easily noted in the individual profile. We present, therefore, in Figure 5 a single profile, chosen because its properties are readily evident and also because it is similar to the overall average. The features can be made to emerge more prominently if the aerosol coefficients are used to compute a turbidity profile, $t_p(h, \lambda_1) = \beta_p(h, \lambda_1) / \beta_r(h, \lambda_1)$, where β_p and β_r are the aerosol and Rayleigh coefficients respectively and $\lambda_1 = 0.55\mu$ (Figure 6).

Since volcanic dust in the atmosphere can have a residence time of several years, the effects of the Mt. Agung eruption (March 1963) must be considered. The direct measurements of Junge, Chagnon, and Manson (1961), Friend (1965), Mossop (1964), and Rosen (1968), collectively considered, before and after this event, show evidence of change in the stratospheric aerosol content. The observations of the twilight sky by Volz (1965) and Meinel and Meinel (1964) also show augmentation of stratospheric particulates. Since the searchlight probing measurements yielded absolute values of aerosol attenuation coefficients, the most suitable parameter to use for examining this feature quantitatively is the stratospheric aerosol optical thickness for the altitude region between the tropopause and 25 km. The reason for choosing the latter altitude limit will be discussed later. Accordingly, all profiles were placed in time-sequential groups determined by the similarity of the stratospheric dust feature. Then the optical thickness was computed by

$$\bar{\tau} = \frac{1}{n} \sum_{i=1}^n \sum_{h_1}^{h_2} \bar{\beta}'(h) \Delta h, \quad (7)$$

where n is the number of profiles in the group, h_1 is the altitude of the tropopause, h_2 the 25 km altitude, $\bar{\beta}'$ the mean aerosol attenuation coefficient (within each profile) for the altitude interval, and Δh the altitude intervals used for computing the profiles. The results of this computation are presented in Table 3. The tabulation demonstrates a relatively high level of stratospheric dust for the December 1963 to March 1964 period. Beginning with April 1964, dust abatement and a generally stabilized level are in evidence. The mean optical thickness of Group (B+C+D) is 26 percent less than that of Group A. Since Group A entails a period of abnormally high aerosol content, its profiles are not representative. These results are in satisfactory agreement with the findings from the direct measurements of the authors mentioned.

| Group | Period (Inclusive) | Number of Profiles | Mean Optical Thickness (approx. 12-25 km) |
|-------|-----------------------|-----------------------|--|
| A | Dec 1963 – Mar 1964 | 40 | 3.1×10^{-2} |
| B | Apr 1964 – Sep 1964 | 50 | 2.2 |
| C | Oct 1964 – Nov 1964 | 10 | 2.7 |
| D | Dec 1964 – Apr 1965 | 19 | 2.4 |
| B+C+D | Apr 1964 – Apr 1965 | 79 | 2.3 |

The considerations discussed above justify the selection of the Group (B+C+D) profiles as a basis for developing representative aerosol attenuation parameters. It will be convenient to designate the 79 profile average for $\lambda_1 = 0.55\mu$ as $\bar{\beta}_p(h, \lambda_1)$ (Figure 7). This profile can be extended to encompass a larger altitude range by using the scale height relationship,

$$\bar{\beta}_p(h_2, \lambda_1) = \bar{\beta}_p(h_1, \lambda_1) \exp \left[- \frac{(h_2 - h_1)}{H_p} \right] . \quad (8)$$

Penndorf's study (1954) shows that for the lowest 5 km, the aerosol coefficients fall off exponentially with a scale height $0.97 < H_p < 1.4$ km. We resort to the use of his mean value, $H_p = 1.2$ km, to extend the $\bar{\beta}_p(h, \lambda_1)$ profile from 3.7 km to sea level. This results in aerosol coefficients which are identical to those of the 1964 Attenuation Model for altitudes 0 to 3 km (Table 4.11).

Above the convective region, up to the tropopause the aerosol coefficients show a moderate gradient which is in close agreement with Penndorf's analysis (1954) of the vertical distribution of aerosols in the troposphere. Also, this section of the profile is based on high signal to noise measurements and extensive averaging, factors which contribute to its reliability. Additionally, this altitude region, being above the convective layer, is characterized by aerosol conditions which tend to be independent of surface terrain. These considerations suggest that the shape and values of the $\bar{\beta}_p(h, \lambda_1)$ profile for this altitude region are realistic.

Above the tropopause, up to 25 km, the coefficients are larger than those derived for the 1964 Attenuation Model by a factor of about 20 (at 20 km for $\lambda_1 = 0.55\mu$). This difference may be attributed in part to the intrinsic difficulties of converting a size distribution to an optical parameter, that is, establishing the radii limits, particle shape, chemistry, and index of refraction. Relative to profile shape, a turbidity maximum dominates at about 19 km (Figure 8). The measurements of Rosen (1968) and those of Volz (1968) for 1964 to 1968 are in satisfactory agreement

Figure 7. Mean of 79 Low Stratospheric Dust Profiles (Table 3) for April 1964 to April 1965. Aerosol attenuation coefficients, $\bar{\beta}_p(h, \lambda_1)$; standard deviation limits attributable to error and atmospheric variations; $\lambda_1 = 0.55\mu$; ++++ measurements with searchlight probing

Figure 7. Mean of 79 Low Stratospheric Dust Profiles (Table 3) for April 1964 to April 1965. (See caption for Figure 7)

with the mean optical thickness and shape of the Group (B+C+D) profiles, Table 3. Also their results show that the stratospheric dust level has remained approximately constant from 1964 to the time of this writing. The $\bar{\beta}_p(h, \lambda_1)$ curve (Figure 7) shows this dust feature as the knee of the profile rather than a massive layer feature indicated by the turbidity profile. This conceptual relationship suggests that over-emphasis is possible when dealing only with turbidity profiles.

The turbidity profile shows an upper stratospheric maximum with its lower terminus at 25 km. This altitude then, was the basis for choosing the upper stratospheric dust limit in Eq. (7). The maximum at 26 km occurs with sufficient frequency to be easily identified in the turbidity profile. The existence of such an aerosol concentration above 20 km is supported by the analysis of satellite photography reported by Mateer, Dave, Dunkelman, and Evans (1967).

To establish upper altitude aerosol coefficients, a least square fit was computed for $\bar{\beta}_p(h, \lambda_1)$ from 26 to 32 km (Figure 9). The result, $H_p = 3.75$ km (in effect derived from 790 measurement points), was used in Eq. (8) to extend the values to 50 km. Miller (1967) obtained $H_p = 3.25$ km from a thorough analysis of rocket measurements acquired in 1964 for this altitude region. The overall profile from sea level to 50 km is presented in Figure 10 (Table 4.11). Since the

Figure 9. Expanded Scale for 26 to 32 km Altitude Region Showing $H_p = 3.75$ km for 79 Profile Mean; Aerosol Attenuation Coefficients, $\beta_p(h, \lambda_1)$ vs Altitude; Least Square Fit Used to Extrapolate to 50 km; $\lambda_1 = 0.55\mu$

Figure 10. Comparison of Profiles. Aerosol attenuation coefficients $\beta_p(h, \lambda_1)$, with molecular $\beta_r(h, \lambda_1)$. The 1964 profile shows interpolation between 5 to 10 km; $\lambda_1 = 0.55\mu$

turbidity is proportional to the mixing ratio, the diminishing values for the extrapolation imply the aerosol source exists below 30 km. Should the source be of meteoric origin, the mixing ratio would tend to be constant or increase for altitudes 30 to 50 km.

Thus far we have selected a set of measurements for $\lambda_1 = 0.55\mu$ and provided reasons for its use. It would be in order now to examine some expressions leading to corresponding aerosol profiles for other wavelengths. If we consider a real atmosphere, the aerosol sizes within unit volume can be described by a size distribution function, $\psi(r)$. Various size distribution functions are in use: the Junge type power law (1963) with a choice of exponents discussed in detail by Bullrich (1964), a similar distribution modified by gaps observed by Fenn (1964), a log-Gaussian distribution used by Foitzik (1965), a composite distribution with components from several types. The optical-particle size relationship utilizes $\psi(r)$ such that

$$\beta_p(m, r, \lambda) = \int_{N_{r2}}^{N_{r1}} \sigma_p(m, r, \lambda) dN_p(r) \quad , \quad (9)$$

$$dN_p = N_o \psi(r) dr \quad , \quad (10)$$

$$N_o(h) = C N_p(h) \quad . \quad (11)$$

β_p is the aerosol attenuation coefficient, m is the index of refraction, N_{r1} and N_{r2} are the aerosol number density limits established by the radii limits r_1 and r_2 , σ_p is the aerosol cross section for each particle, N_p is the total number of particles between r_1 and r_2 . For a given altitude, N_o actually is proportional to the particle number density between r_1 and r_2 . Since the same size distribution function applies to all altitudes (an assumption), Eqs. (9), (10), and (11) are combined

$$\beta_p(h, \lambda) = C N_p(h) \int_{r_1}^{r_2} \sigma_p(r, \lambda) \psi(r) dr \quad . \quad (12)$$

Here, $C N_p(h)$ is placed outside the integral which now contains only factors that are independent of altitude; also, m is removed because subsequent considerations will pertain to particles without any distinction in refractive index. If Eq. (12) is normalized to sea level conditions, the integral cancels out. Then generally for the various wavelengths λ , and specifically for $\lambda_1 = 0.55\mu$, we have

$$\frac{\beta_p(h, \lambda)}{\beta_p(0, \lambda)} = \frac{\beta_p(h, \lambda_1)}{\beta_p(0, \lambda_1)} = \frac{N_p(h)}{N_p(0)} \quad (13)$$

or

$$\beta_p(h, \lambda) = \frac{\beta_p(0, \lambda)}{\beta_p(0, \lambda_1)} \cdot \beta_p(h, \lambda_1) \quad (14)$$

Equation (13) has been derived in this manner to demonstrate its compatibility with particle size considerations. Sea level conditions have been researched extensively by Curcio and Durbin (1959), Curcio, Knestrick, and Cosden (1961), Knestrick, Cosden, and Curcio (1961), Dunkelman (1952), Baum and Dunkelman (1955). The $\beta_p(0, \lambda)$ values for a 25 km M.R., based on the results of these authors, are shown in Figure 11 (see also Elterman, 1964). Utilizing these results, in conjunction with the $\bar{\beta}_p(h, \lambda_1)$ profile (Table 4.11), all requirements for the right-hand side of Eq. (14) are satisfied and an array of aerosol attenuation coefficients can be computed for all altitudes and wavelengths of interest.

The aerosol optical thickness from sea level to altitude h , $\tau_p(h, \lambda)$, and the aerosol optical thickness from some altitude h to space, $\tau_p'(h, \lambda)$, are included in the model tabulations. The expressions for deriving these parameters have the same form as Eqs. (4) and (5).

Figure 11. Aerosol Attenuation Coefficients $\beta_p(0, \lambda)$ vs Wavelength at Sea Level for a Meteorological Range Approximating 25 km.

A - derived from Baum and Dunkelman (1955)

B - contained in Curcio, Knestrick, and Cosden (1961)

5. ATMOSPHERIC EXTINCTION

In this section, three sets of extinction parameters are considered: extinction coefficient, extinction optical thickness from sea level to a desired altitude, and extinction optical thickness from a desired altitude to space.

The atmospheric extinction coefficient β_{ext} is the sum of all the attenuating components:

$$\beta_{\text{ext}}(h, \lambda) = \beta_r(h, \lambda) + \beta_s(h, \lambda) + \beta_p(h, \lambda) \quad . \quad (15)$$

The extinction optical thickness from sea level to altitude h , $\tau_{\text{ext}}(h, \lambda)$, and the extinction optical thickness from some altitude h to space, $\tau'_{\text{ext}}(h, \lambda)$, are included in the tabulations of the attenuation model. The expression for deriving these parameters has the same form as Eqs. (4) and (5).

6. EXPLORATORY TRANSMISSION CALCULATIONS

Using the derived tabulations that follow, some exploratory calculations with extinction parameters (for any of the wavelengths) are demonstrated. Rayleigh, aerosol, and ozone parameters can be used similarly.

For horizontal transmission (T_h) over a path (d) at any altitude (h), the extinction coefficient

$$T_h = \exp \left[- \beta_{\text{ext}}(h, \lambda) \cdot d \right] \quad . \quad (16)$$

For vertical and slant-path transmission from sea level to a given altitude, at zenith angle θ for all wavelengths of interest

$$T_{0-h} = \exp \left[- \tau_{\text{ext}}(h) \cdot \sec \theta \right] \quad . \quad (17)$$

For vertical and slant-path transmission between two altitudes above sea level

$$T_{\Delta h} = \exp \left[- \left[\tau_{\text{ext}}(h_2) - \tau_{\text{ext}}(h_1) \right] \cdot \sec \theta \right] \quad . \quad (18)$$

For vertical and slant-path transmission from a given altitude out into space

$$T_{h-\infty} = \exp \left[- \tau'_{\text{ext}}(h) \sec \theta \right] \quad . \quad (19)$$

7. CONCLUDING REMARKS

The procedure for developing the aerosol attenuation profile is summarized as follows:

- (1) Various studies were compared and of these a set of measurements selected.
- (2) The choice of measurements (comprising 119 profiles from 2.76 to 34.4 km) was examined statistically. This resulted in the elimination of 40 profiles (December 1963 to March 1964 inclusive) characterized by a high volcanic dust component.
- (3) The mean of the 79 remaining profiles was extended to sea level and to 50 km respectively by reasonably supported extrapolations.
- (4) The overall profile then was developed laterally to obtain 21 additional profiles for the wavelengths of interest.

A significant aspect of the procedure is that the wavelength-height array of parameters was derived independently of the assumptions associated with conversion of a size distribution to an optical parameter.

For most purposes, calculations using the new parameters will be affected only moderately. For example at $\lambda_1 = 0.55\mu$, the 1964 Attenuation Model provides an extinction optical thickness, $\tau_{\text{ext}} = 0.331$, for a vertical air mass. The new parameters yield $\tau_{\text{ext}} = 0.379$, resulting in a transmission change of about 3-1/2 percent. However, for long path horizontal transmission calculations above 5 km and for long slant-path calculations entailing large zenith angles, the new aerosol parameters can function more significantly.

As mentioned previously, the Rayleigh and ozone parameters are unchanged.

8. TABULATION OF PARAMETERS

Tables 4.1 to 4.22, which follow, comprise the atmospheric attenuation model. Exponents are in computer notation; for example, read $2.86-3 = 2.86 \times 10^{-3}$ and $2.86\ 3$ as 2.86×10^3 .

| 13. ABSTRACT <p>An atmospheric attenuation model for the ultraviolet, visible, and infrared was developed in 1964, based on scattering (molecules and aerosols) and ozone absorption. Since then more measurements have been made and our knowledge of aerosol attenuation has widened. These circumstances result in attenuation model changes which are relatively unimportant for most exploratory calculations. They can be significant, however, for long slant-path high-altitude applications entailing large zenith angles, factors which characterize, for example, the measurement geometries of rockets and satellites. Accordingly, a revision of the 1964 Attenuation Model is warranted.</p> <p>In this paper the optical parameters are computed spectrally and with altitude as follows: (1) pure air attenuation parameters are determined by utilizing Rayleigh scattering cross sections with molecular number densities from the standard atmosphere; (2) ozone absorption parameters are derived based on Vigroux's coefficients applied to a representative atmospheric ozone distribution; (3) seven sets of aerosol measurements are compared and a profile of aerosol attenuation coefficients vs altitude is developed. Attenuation coefficients and optical thickness due to molecular, aerosol, and ozone attenuation are computed and tabulated individually so that the influence of each can be compared. The newly derived tabulations permit various exploratory calculations, including horizontal, vertical, and slant-path transmission at kilometer intervals to an altitude of 50 km, individually for each attenuating component or for overall atmospheric extinction (molecular + ozone + aerosol).</p> | | |
